## ABSTRACT

We report the discovery of one unique cataclysmic variable drawn from the Hamburg Quasar Survey, HS 2331+3905. Follow-up observations obtained over three years unveiled a very unusual picture. The large amplitude 3.5 h radial velocity variations obtained from our optical spectroscopy is not the orbital period of the system, as one would normally expect. Instead, extensive CCD photometry strongly suggests that HS 2331+3905 is a short orbital period cataclysmic variable with  $P_{\text{orb}} = 81.09$  min, containing a cold white dwarf which appears to exhibit ZZ Ceti pulsations.

**Key Words:** STARS: BINARIES:CLOSE — STARS: CATAclysmic VARIABLES — STARS: INDIVIDUAL: HS 2331+3905

## 1. INTRODUCTION

HS 2331+3905 (HS 2331 thereafter) was selected as a cataclysmic variable (CV) candidate on the basis of its spectral characteristics in the Hamburg Quasar Survey (HQS; Hagen et al. 1995; Gänsicke et al. 2002). The identification spectrum of HS 2331 contains broad double-peaked Balmer emission lines, clear signs of the presence of an accretion disc, flanked by extremely broad absorptions troughs, indicating that this CV contains a relatively cold white dwarf. The red part of the spectrum does not contain any spectral features that could be ascribed to the emission of the secondary. Here we report follow-up (ground and space) photometry and spectroscopy of HS 2331, obtained over a three year period after its identification.

## 2. OBSERVATIONS

The left panel of Fig. 1 shows sample light curves of HS 2331 obtained from differential CCD photometry. The morphology of the photometric modulation is best described by a double-humped pattern with a period of  $\sim 80$  min, with narrow dips centred on the observed minima between humps, which we identify as grazing eclipses. The higher time resolution data, in the middle and bottom panel of the same figure, reveal additional variability on time scales of 5 min and 1 min. A period analysis of the entire CCD photometry of HS 2331 - more than 20 000 data points

- confirms the multiperiodic variability directly seen in the light curves. The likely orbital period derived from the period analysis, and ratified by folding all the data over it, is  $P_{\text{orb}} = 81.0852 \pm 0.0002$  min. In addition to the orbital period, the period analysis also reveals strong peaks at 83.38 min, 5.61 min and 1.12 min. The 83.38 min is in the right frequency range to represent a superhump period (i.e. 1–2% longer than  $P_{\text{orb}}$ ). The power spectra around the 5.61 min and 1.12 min signals show an extremely complex structure indicative of a superposition of many frequencies. This type of structures are found in ZZ Ceti pulsators which can be explained by a number of non-radial pulsations modes, their harmonics, and various linear combinations of modes (e.g. Kotak et al. 2002).

Radial velocity variations of the Balmer and He I emission lines revealed yet another period at  $\sim 3.5$  h. This period seems to drift throughout the three years of observations, and we could not identify a single period that will satisfactorily fold all the available radial velocity data. We conclude that a persistent large-amplitude radial velocity variation with a period  $\sim 3.5$  h is present in HS 2331, however, this variation is not coherent but its period drifts on time scales of days.

In addition to optical spectroscopy we have obtained a *HST* STIS far-ultraviolet (*FUV*) spectrum of HS 2331. The *FUV*-optical spectra combined with the 2-MASS *JHK* colours of HS 2331 allow us to confirm the presence of a low-temperature white dwarf of  $T_{\text{wd}} \sim 11\,000$  K, and to constrain the spectral type of the secondary to be later than M9, consistent with the short orbital period of the system (see right panel of Fig. 1). The accretion disc contri-

Fig. 1. *Left panel:* Samples of the light curves of HS 2331 obtained from differential CCD photometry. The names and numbers indicate the observatory and time resolution used in each of the observations respectively. *Right panel:* Combination of *FUV*, optical spectra and 2MASS colours of HS 2331 (dark line and filled circles) plotted with the best three-component model fit (grey line and open circles). See text for details.

bution to the spectral energy distribution of HS 2331 was matched with a 6500 K isothermal and isobaric slab and a surface density  $1.81 \times 10^{-2} \text{ g cm}^{-2}$ . The distance of the system estimated from the white dwarf model fit is  $\sim 100 \text{ pc}$ , consistent with the large proper motion of the star,  $\mu = 0.14''$ .

### 3. DISCUSSION

We have discovered a short orbital period system, HS 2331, as part of the HQS quest for new CVs. The orbital period of HS 2331,  $P_{\text{orb}} = 81.09 \text{ min}$ , was primarily defined by the detection of coherent eclipses. From our three years of photometric data, HS 2331 appears to be a permanent superhumper with  $P_{\text{SH}} = 83.38 \text{ min}$ . The light curves of HS 2331 display double-humps with a period that is exactly half the orbital period (evident from a direct inspection of the light curves in the left panel of Fig. 1), suggesting that we are seeing some sort of symmetric structure, such as e.g. two bright spots. In addition, HS 2331, exhibits the photometric behaviour typical of ZZ Ceti pulsators, showing multifrequency variability in the range  $\sim 60 \text{ s}$  to  $\sim 300 \text{ s}$ . The white dwarf temperature derived from our fit, 11 000 K, is well within the instability strip for ZZ Ceti pulsators. In order to disentangle the multiperiodic signature of the likely white dwarf pulsator in HS 2331, we need to organize a multi-site observing campaign to obtain long, continuous stretches of high time resolution photometry.

All in all, the pieces of the jigsaw seems to come together, and we are beginning to understand the nature of HS 2331. There are nevertheless, several points that we still need to address. The fact that the dominant radial velocity variability does not cor-

respond to the orbital period of the system is particularly disconcerting. At present, we have no explanation for this phenomenon, nor for the physical significance of the 3.5 hr radial velocity period. We are not aware of any other system suffering from this problem, but the reason for this may be that periods determined from radial velocity studies are usually adopted unquestioned as reflecting the corresponding orbital periods.
